The report

Introduction

In 1958, Texas Instruments (TI) employee Jack Kilby invented the integrated circuit (IC)¹ – a circuit compressed into a tiny package. ICs now make 80% of TI's revenue². Today, we often regard them as magic black boxes. However, the inner workings of these “chips” are fascinating and under-appreciated.

ICs are made of a tiny silicon and copper ‘die’ encased in plastic³. To make them, silicon is etched with microscopic electronic components by using photo-resistive chemicals and UV light⁴.

Disassembly

We disassembled (‘decapped’) a TI SN7404 hex NOT gate to better understand how it worked. A NOT gate is a basic logic gate which outputs the inverse of its input (figure 9). We chose this IC because it was simple and available.

To remove the casing, we initially soaked the IC in nitric acid heated to 90°C (194° F). This was not very effective and reacted with the copper producing toxic nitrogen dioxide fumes. Sulfuric acid of the same temperature worked better and slowly dissolved the casing, leaving the die. Hot acid is dangerous, so glasses were worn, a fume hood was used, and a chemistry teacher supervised us.

Analysis

The die was approximately 1.5mm (about 0.06”) square and was mounted on a comparatively large piece of metal, aiding handling. It was transferred to a microscope equipped with a camera and photographed at 100x zoom. We believe that our images are primarily of the metal connective layer, rather than the silicon, as both our dissolving and microscopy was somewhat rudimentary.

The die has several gold bond wires attached, which connected it to the large wires leading out of the IC. Each of the 6 NOT gates have an input and output wire, and are connected to shared ground and power rails (a total of 14 pins). It made sense that there were 6 clear regions on the die – one for each gate.

Reverse-engineering the whole integrated circuit is difficult, however some components are relatively easy to identify, such as transistors. We were aided by a professional die shot of an SN7405 (a similar IC) and circuit diagrams from the SN7404 and SN7405 datasheets^{5 6}. This helped us to understand the components we were looking at, allowing us to produce a bill of materials matched to the die.

A NOT gate can be made many ways. Software could be used, reducing the physical part count (figure 10), or discrete components could be utilized instead. This showed us how ICs aren't magic – their internal components can be understood like any circuit.

Parts List A – Main Integrated Circuit

Part Name	Qty	Description	Photograph
Plastic housing	1	Protects the delicate die from the outside conditions	See figure 1
Die	1	A minute silicon and copper plate that houses the transistors, diodes, resistors and other components that make up the circuit. See Parts List B	See figure 6
Bond wire	14	A tiny gold wire that connects the die to the large wires leading out of the integrated circuit package.	
Wires ('pins')	14	Copper wires leading out of the IC, allowing it to be connected to the greater circuit.	

Part List B – Components on Die

Six NOT gates, each containing the following				
Part Name	Qty	Description	IC photo	Discrete component
Transistor (bipolar junction)	4	Can be used for many applications including a voltage or current-controlled switch or a voltage amplifier. Consists of 2 P-N type silicon junctions. In our photos, looks like 3 distinct wires nearby, which connect to each of the N, P, and N pieces of silicon making up the junction. Note most modern ICs use CMOS instead of bipolar junction transistors, so they look different. BJTs are simpler, so we chose an IC using them.		
Diode	2	A component that only lets current flow one way. Consists of 1 P-N type silicon junction. In our photos, looks like 2 distinct nearby wires connecting to the P and N pieces of silicon.		
Resistor	4	A component that restricts the amount of current able to flow.	Indistinguishable from a wire in our photos	
Wire	N/A	Copper. Connects components together.
